## Received 6 September 1990

A determination of the partial width $\Gamma_{\mathrm{c} \overline{\mathrm{c}}}$ of the $\mathcal{Z}^{0}$ boson into charm quark pairs is presented, based on a total sample of 36900 $Z^{0}$ hadronic decays measured with the DELPHI detector at the LEP collider. The production rate of co events is derived from the inclusive analysis of charged pions coming from the decay of charmed meson $\mathrm{D}^{*+} \rightarrow \mathrm{D}^{0} \pi^{+}$and $\mathrm{D}^{*-} \rightarrow \overline{\mathrm{D}}^{0} \pi^{-}$where the $\pi^{ \pm}$is constrained by kinematics to have a low $p_{\mathrm{T}}$ with respect to the jet axis. The probability to procedure these $\pi^{ \pm}$from $\mathrm{D}^{* \pm}$ decay in cé events is taken to be $0.31 \pm 0.05$ as measured at $\sqrt{s}=10.55 \mathrm{GeV}$. The measured relative partial width $\Gamma_{\mathrm{cc}} / \Gamma_{\mathrm{h}}=0.162 \pm$ 0.030 (stat.) $\pm 0.050$ (syst.) is in good agreement with the standard model value of 0.171 . Together with our previous measurement of the total hadronic width $\Gamma_{\mathrm{h}}$ this implies $\Gamma_{\mathrm{cc}}=282 \pm 53$ (stat.) $\pm 88$ (syst.) MeV .

## 1. Introduction

Measurements of the hadronic and leptonic partial widths of the $Z^{0}$ boson have already been reported by the DELPHI Collaboration [1-3]. A more detailed study of the standard model will need a determination of the $\mathrm{Z}^{0}$ boson decays into all known quark flavours. This paper presents a determination of the cross section ratio
$R_{\mathrm{c} \overline{\mathrm{c}}}=\frac{\sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow \mathrm{c} \overline{\mathrm{c}}\right)}{\sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow \text { hadrons }\right)}$ at $\sqrt{s}=91 \mathrm{GeV}$.
Charmed mesons are usually identified via the reconstruction of their decay products. However such an identification has an efficiency of only a few per cent due to the small branching ratios involved. Therefore another technique is applied here which has been already used at lower energies [ 4,5 ] and which does not require the reconstruction of exclusive final states. It is well suited to our present limited statistics.

The charm quark is known to fragment predominantly into a charmed vector meson $\mathrm{D}^{*}$ which carries a large fraction of the quark energy [5-8]. In the $\mathrm{D}^{*+} \rightarrow \mathrm{D}^{0} \pi^{+}$decay ${ }^{\# 1}$, whose branching ratio is about $50 \%$, the residual energy is 6 MeV and thus the maximum transverse momentum of the $\pi^{+}$with respect to the $\mathrm{D}^{*+}$ is only $40 \mathrm{MeV} / \mathrm{c}$. Due to the relative transverse momentum of the $\mathrm{D}^{*+}$ with respect to the charm quark and due to the smearing in the charm quark jet reconstruction, the mean transverse momentum $p_{\mathrm{T}}$ of the $\pi^{+}$with respect to its jet axis will be around $65 \mathrm{MeV} / \mathrm{c}$ whereas it is about $300 \mathrm{MeV} / \mathrm{c}$ for ordinary hadrons in the fragmentation of the jet.

For this reason the $p_{\mathrm{T}}^{2}$ distribution of charged particles relative to the jet axis will exhibit an accumulation of events at low transverse momentum which is characteristic of the decay of charmed meson $\mathrm{D}^{*+} \rightarrow \mathrm{D}^{0} \pi^{+}$in cce events. Taking the probability for a charm quark to fragment into a $\mathrm{D}^{*+}$ from a measurement at $\sqrt{s}=10.55 \mathrm{GeV}$ [6], and assuming this is unchanged at 91 GeV we shall derive the ratio $R_{\mathrm{cc}}$. This assumption is in accord with another measurement at $\sqrt{s}=29 \mathrm{GeV}$ [8] and with Lund model predictions.

[^1]
## 2. The DELPHI detector

The components of the apparatus relevant for the present analysis have already been described in refs. [ 1,2$]$. Some of its main features are recalled here. The charged particles are measured in a 1.2 T magnetic field ( 0.7 T for $14 \%$ of the total data sample) by a set of three cylindrical tracking detectors: the Inner Detector (ID) covers radii from 12 to 28 cm , the Time Projection Chamber (TPC) from 30 to 122 cm , and the Outer Detector (OD) from 198 to 206 cm . For track reconstruction in the TPC, at least four space points are available for polar angles between $21^{\circ}$ and $159^{\circ}$, and up to sixteen space points between $39^{\circ}$ and $141^{\circ}$.

In the Barrel part, covering polar angles between $40^{\circ}$ and $140^{\circ}$, the trigger on hadronic events is made of redundant subtriggers based on the ID and OD chambers, and on the scintillation counters of the HPC (High density Projection Chamber) and ToF (Time of Flight). The trigger efficiency was found to be larger than $99.9 \%$ for hadronic events with a sphericity axis between $50^{\circ}$ and $130^{\circ}$. In the forward region, covering polar angles between $15^{\circ}$ and $35^{\circ}$ and between $145^{\circ}$ and $165^{\circ}$, the number of $Z^{\circ}$ events was enhanced by also triggering on an energy deposition of at least 3 GeV in each endcap of the FEMC (Forward Electromagnetic Calorimeter).

## 3. Event selection

This analysis relies only on tracks from charged particles, using all the data collected from September 1989 up to May 1990 during the three scanning periods around the $Z^{0}$ peak (the mean center-of-mass energy was 91 GeV ). Charged particles were selected as in refs. [1,2]:

- polar angle $\theta$ between $20^{\circ}$ and $160^{\circ}$;
- momentum $p$ between $0.1 \mathrm{GeV} / c$ and $50 \mathrm{GeV} / c$;
- track length above 30 cm ;
- relative error on momentum measurement below $100 \%$;
- projection of impact parameter below 4 cm in the plane transverse to the beam direction;
-distance from the origin below 10 cm along the beam direction.

Hadronic events were retained if they had at least
five charged particles and if the invariant mass of all charged particles was larger than $12 \mathrm{GeV} / c^{2}$. These requirements keep $92 \%$ of hadronic decays of the $\mathrm{Z}^{0}$ and reduce any background to a negligible level. The resulting data sample corresponds to $10100(26800)$ hadronic $\mathrm{Z}^{0}$ s accumulated in 1989 (1990), the integrated luminosity being 540 (1200) $\mathrm{nb}^{-1}$ respectively.
A detailed and reliable simulation is essential in order to establish the selection efficiency for charm quark final states. The quark fragmentation is based on the Lund parton shower model (version Jetset 6.3) [9]. The Monte Carlo simulation of the detector itself includes secondary interactions and collection of electronic signals, allowing the generated events to be treated in the same analysis chain as the real data. We have shown that this simulation describes the distribution of various topological variables of our hadronic data well [10].
Background to $\pi^{+}$mesons from $\mathrm{D}^{*+} \rightarrow \mathrm{D}^{0} \pi^{+}$decays in ce events comes from all other processes giving low $p_{\mathrm{T}}$ particles with respect to their jet axis. Charmed $\mathrm{D}^{*+}$ mesons coming from the decay of bottom hadrons have a lower momentum than those originating from the primordial charm quark. Photons from $\pi^{0}$ decays can convert inside the detector and the electrons from pairs have a low $p_{\mathrm{T}}$ at low momentum. But above an energy of about 1 GeV , the simulation shows that their average $p_{\mathrm{T}}$ is around 200 $\mathrm{MeV} / c$ which is close to the $p_{\mathrm{T}}$ of ordinary hadrons.

Charged particles are clustered into jets by using the standard LUCLUS algorithm of the Lund package [9]. The jet axis is not defined as the sum of momenta of all charged particles in this jet, out as the thrust axis of the jet computed with momentum squared weight [4]. Simulation showed that this definition increases the low $p_{\mathrm{T}} \pi^{+}$signal to noise ratio by about $20 \%$.

In order to enhance the signal of $\pi^{+}$mesons from $\mathrm{D}^{*+}$ decays, charged particles were retained if they had:

- momentum $p$ between 1.5 and $2.5 \mathrm{GeV} / c$;
- projection of impact parameter below 2 cm in the plane transverse to the beam direction.
The jet they belonged to had then to satisfy the following requirements:
- at least three charged particles inside the jet;
- at least one particle inside the jet with a momentum larger than $p$;
- polar angle of jet axis fulfilling $\left|\cos \theta_{\text {jet }}\right|<0.8$;
- ratio $Z_{\text {jet }}=E_{\text {jet }} / E_{\text {hemi }}>0.9$;
where $E_{\text {jet }}$ and $E_{\text {hemi }}$ are respectively the total energy of the jet and the sum of the energies of all charged particles in the same sphericity hemisphere.
The $1.5 \mathrm{GeV} / c$ momentum cut reduces background from $\mathrm{b} \overline{\mathrm{b}}$ production, photon conversion and particles from soft fragmentation. Few $\pi^{+}$mesons from $\mathrm{D}^{*+}$ decay are expected above $2.5 \mathrm{GeV} / c$. The cut on the impact parameter reduces the remaining $\mathrm{e}^{ \pm}$contamination. The cuts on the multiplicity inside the jet and on the jet axis direction restrict consideration to jets in which the charged particles are well measured. The cut on $Z_{\text {jet }}$ is intended to remove jets from gluon radiation and to enhance the signal from the primary charm quark.

## 4. Analysis of the $\boldsymbol{p}_{\mathbf{T}}^{\mathbf{2}}$ distributions

The previous cuts were applied to a Monte Carlo simulation of $34500 \mathrm{q} \bar{q}$ events. The $p_{\mathrm{T}}^{2}$ distribution of charged particles with respect to their jet axis is presented in fig. la for cc events and in fig. lb for other $q \bar{q}$ events (where $q$ stands for $u, d, s$ or $b$ quark flavours). The cè sample shows a clear accumulation of events with low $p_{\mathrm{T}}^{2}$, not apparent in the non-charm sample. According to the simulation, the contribution of low $p_{\mathrm{T}}^{2}$ charged particles from $\mathrm{b} \overline{\mathrm{b}}$ production happens to be compensated by a depletion in the $p_{\mathrm{T}}^{2}$ distribution associated to light quark pairs. This remark applies in particular to the $\pi^{ \pm}$produced in the decay of $\mathrm{D}^{* \pm}$ originating from beauty hadrons. It reflects a slightly worse angular reconstruction of the jet axis, as defined in section 3 , in the case of $u, d, s$ type quarks.
The amount of $\mathrm{D}^{*+} \rightarrow \mathrm{D}^{0} \pi^{+}$decays contributing to fig. la was evaluated as follows:

- first the $p_{\mathrm{T}}^{2}$ distribution of the $\pi^{+}$from $\mathrm{D}^{*+} \rightarrow \mathrm{D}^{0} \pi^{+}$ decay in cc̄ events (hatched area in fig. 1a) was fitted for $p_{\mathrm{T}}^{2}<0.01(\mathrm{GeV} / c)^{2}$ with a simple exponential:
$S\left(p_{\mathrm{T}}^{2}\right) \sim\left(N_{\mathrm{S}}^{0} / B^{2}\right) \exp \left(-p_{\mathrm{T}}^{2} / B^{2}\right)$,

Fig. 1. $p_{\mathrm{T}}^{2}$ distribution of charged particles with respect to their jet axis for a Monte Carlo simulation of $34500 \mathrm{q} \overline{\mathrm{q}}$ events after the cuts specified in the text. Curves are the result of a fit $S\left(p_{\mathrm{T}}^{2}\right)+F_{1}\left(p_{\mathrm{T}}^{2}\right)$ performed for $p_{\mathrm{T}}^{2}<0.25(\mathrm{GeV} / c)^{2}$ (full line) and the extrapolation of $F_{1}\left(p_{\mathrm{T}}^{2}\right)$ (dashed line). The simulation is performed (a) for cic events only, where $\pi^{+}$from $\mathrm{D}^{*+} \rightarrow \mathrm{D}^{0} \pi^{+}$ and $\pi^{-}$from $\mathrm{D}^{*-} \rightarrow \overline{\mathrm{D}}^{0} \pi^{-}$decays are presented in the hatched histogram; or (b) for all quark flavours except charm quark, where $u \bar{u}+d \bar{d}+s \bar{s}$ and $b \bar{b}$ contributions are presented in the upper and in the hatched histograms respectively.
with the normalization $N_{\mathrm{s}}^{0}$ and the slope $B$ left free, we found $B=65 \pm 3 \mathrm{MeV} / c$ and $N_{\mathrm{S}}^{0}=366 \pm 22 \pi^{ \pm}$ tracks;

- with the slope $B$ fixed, the distribution in $p_{\text {T }}^{2}$ of the Monte Carlo events were fitted over the range $0<$ $p_{\mathrm{T}}^{2}<0.25(\mathrm{GeV} / c)^{2}$ as the sum $S\left(p_{\mathrm{T}}^{2}\right)+F_{i}\left(p_{\mathrm{T}}^{2}\right)$
where $F_{i}$ describes the long-range smooth $p_{\mathrm{T}}^{2}$ distribution. The sensitivity of the fits to the shape of the full $p_{\mathrm{T}}^{2}$ distribution was evaluated by trying the following two functions with three free parameters each:
$F_{1}\left(p_{\mathrm{T}}^{2}\right) \sim a+b \exp \left(-p_{\mathrm{T}}^{2} / c^{2}\right)$,
$F_{2}\left(p_{\mathrm{T}}^{2}\right) \sim \frac{a^{\prime}}{1+b^{\prime} p_{\mathrm{T}}^{2}+c^{\prime} p_{\mathrm{T}}^{4}}$.
The fit results are illustrated in fig. 1 and in table 1 for our Monte Carlo simulation. Both shapes correctly describe the non-charm qā sample without significant signal; for the cé sample each fit $S+F_{i}$ gives an amount of signal $N_{\mathrm{S}}$ in agreement with the value $366 \pm 22$ expected.
For the selected sample of real data ( 36900 hadronic $Z^{0}$ events) fig. 2 shows the $p_{\text {T }}^{2}$ distributions of charged particles for two momentum intervals:
$1.5<p<2.5 \mathrm{GeV} / c$ (a) ,
$3<p<4 \mathrm{GeV} / c$ (b).
At high momentum (b) we see no significant accumulation at low $p_{\mathrm{T}}^{2}$ in agreement with the Monte Carlo expectation, while in the momentum range (a) an excess is apparent. Following the same procedure as for Monte Carlo events, the distribution displayed in fig. 2 a was fitted for $p_{\mathrm{T}}^{2}<0.25(\mathrm{GeV} / c)^{2}$ with the shape $S+F_{i}$ where the slope $B=65 \mathrm{MeV} / c$ is fixed and where the three parameters in $F_{i}$ are left free. This fit yields $N_{\mathrm{s}}=336 \pm 68\left(\chi^{2} / \mathrm{DF}=125 / 96\right)$ with $F_{1}$ and $N_{\mathrm{S}}=426 \pm 76\left(\chi^{2} / \mathrm{DF}=128 / 96\right)$ with $F_{2}$. The average of these two results gives the measured $\pi^{+}+\pi^{-}$signal: $N_{s}=381 \pm 72$, and the observed difference between the two fits is converted into a systematic error of $\pm 64$ due to the uncertainty on the

Table 1
Fits of $p_{\mathrm{T}}^{2}$ distributions of simulated events ( 34500 generated $\mathrm{q} \overline{\mathrm{q}}$ events).

| Quark flavours | Parametrization | Signal $N_{\mathrm{s}}$ | $\chi^{2} / \mathrm{DF}$ |
| :--- | :--- | :---: | ---: |
| $\mathrm{c} \overline{\mathrm{c}} \rightarrow \mathrm{D}^{*+} \rightarrow \mathrm{D}^{\mathbf{0}} \pi^{+}$ | $S\left(p_{\mathrm{T}}^{2}\right)$ | $366 \pm 22$ | $0.34 / 2$ |
| $\mathrm{c} \overline{\mathrm{c}}$ alone | $S\left(p_{\mathrm{T}}^{2}\right)+F_{1}\left(p_{\mathrm{T}}^{2}\right)$ | $392 \pm 38$ | $97 / 96$ |
|  | $S\left(p_{\mathrm{T}}^{2}\right)+F_{2}\left(p_{\mathrm{T}}^{2}\right)$ | $360 \pm 45$ | $94 / 96$ |

| $\quad$ except $\overline{\mathrm{c}}$ | $S\left(p_{\mathrm{T}}^{2}\right)+F_{2}\left(p_{\mathrm{T}}^{2}\right)$ | $12 \pm 64$ | $110 / 96$ |

Fig. 2. $p_{\mathrm{T}}^{2}$ distribution of charged particles with respect to their jet axis for 36900 hadronic events detected in DELPHI. Curves are the result of a fit $S\left(p_{\mathrm{T}}^{2}\right)+F_{1}\left(p_{\mathrm{T}}^{2}\right)$ performed for $p_{\mathrm{T}}^{2}<0.25$ ( $\mathrm{GeV} / c)^{2}$ (full line) and the extrapolation of $F_{1}\left(p_{\mathrm{T}}^{2}\right)$ (dashed line) or $F_{2}\left(p_{\mathrm{T}}^{2}\right)$ (dash-dotted line). The momentum of the charged particles is in the range $1.5<p<2.5 \mathrm{GeV} / c$ (a) or $3.0<p<4.0 \mathrm{GeV} / c$ (b).
shape of the background. The signal to noise ratio is about 0.14 in the range $p_{\mathrm{T}}^{2}<0.0075\left(\mathrm{GeV} / c^{2}\right)$.

This method relies on an assumed slope for the expected signal $S\left(p_{T}^{2}\right)$. Another method is to fix the background $F_{i}$ by fitting the $p_{\mathrm{T}}^{2}$ distribution for $p_{\mathrm{T}}^{2}$ above $0.0125(\mathrm{GeV} / c)^{2}$. Then the subtraction of the extrapolated background $F_{i}$ from the observed num-

Table 2
Experimental value of the signal $N_{s}^{\prime}$ fitted from the $p_{\mathrm{T}}^{2}$ distribution of 36900 hadronic events, where $N_{s}^{\prime}$ is quoted for $p_{\mathrm{T}}^{2}<$ $0.0075(\mathrm{GeV} / c)^{2}$. Due to the exponential shape of the $p_{\mathrm{T}}^{2}$ distribution of the expected signal, the integrated signal $N_{\mathrm{s}}$ over the full $p_{\mathrm{T}}^{2}$ range is obtained by multiplying $N_{\mathrm{s}}^{\prime}$ by a factor 1.204. The first line shows the values of $N_{s}^{\prime}$ obtained with the shapes $S\left(p_{\mathrm{T}}^{2}\right)+F_{i}\left(p_{\mathrm{T}}^{2}\right)$. The next two lines show the difference between the total number of tracks below $p_{\mathrm{T}}^{2}<0.0075(\mathrm{GeV} / c)^{2}$ and the number given by the extrapolation of the fitted shapes $F_{i}\left(p_{\mathrm{T}}^{2}\right)$ alone.

| $p_{\text {T }}^{2}$ range used in the fit $(\mathrm{GeV} / c)^{2}$ | Shape $S\left(p_{\mathrm{T}}^{2}\right)+F_{1}\left(p_{\mathrm{T}}^{2}\right)$ | Shape $S\left(p_{\mathrm{T}}^{2}\right)+F_{2}\left(p_{\mathrm{T}}^{2}\right)$ |
| :---: | :---: | :---: |
| 0-0.25 | $279 \pm 56$ | $354 \pm 63$ |
|  | Shape <br> $F_{1}\left(p_{\mathrm{T}}^{2}\right)$ alone | Shape $F_{2}\left(p_{\mathrm{T}}^{2}\right)$ alone |
| 0.0125-0.25 | $298 \pm 58$ | $376 \pm 70$ |
| 0.025-0.25 | $310 \pm 60$ | $458 \pm 84$ |

ber of tracks below $0.0075(\mathrm{GeV} / \mathrm{c})^{2}$ gives an estimate $N_{s}^{\prime}$ of the signal. The results of this method applied to the real data are summarized in table 2 for different $p_{\mathrm{T}}^{2}$ ranges. Extrapolating from $p_{\mathrm{T}}^{2}$ larger than $0.0125(\mathrm{GeV} / c)^{2}$, both parametrizations lead to a compatible level of signal below $0.0075(\mathrm{GeV} / c)^{2}$. This holds also for different $p_{\mathrm{T}}^{2}$ intervals, especially for the exponential curve $F_{1}$ whereas the extrapolation from the inverse of polynomial $F_{2}$ presents a larger error. We can conclude that, within statistical errors, the signal shape obtained from Monte Carlo simulation correctly describes real data.

## 5. Measurement of the $\mathbf{Z}^{\mathbf{0}} \rightarrow \mathbf{c c}$ relative partial width

The cross section $R_{c \bar{c}}=\sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow \mathrm{c} \overline{\mathrm{c}}\right) / \sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow\right.$ hadrons) is measured as
$R_{\mathrm{c} \overline{\mathrm{c}}}=\frac{\varepsilon_{\mathrm{h}}}{N_{\mathrm{h}}} \times \frac{N_{\mathrm{S}}}{\varepsilon_{\mathrm{c} \overline{\mathrm{c}}} \times \varepsilon_{\mathrm{S}}}$
where $N_{\mathrm{h}}$ stands for the number of selected hadronic events ( $N_{\mathrm{h}}=36900$ ), $N_{\mathrm{S}}$ is the number of fitted charged particles in the signal at low $p_{\mathrm{T}}^{2}$ ( $N_{S}=$ $381 \pm 72$ ), $\varepsilon_{\mathrm{h}}$ and $\varepsilon_{\mathrm{cc}}$ are the overall efficiencies for hadronic and $c \bar{c}$ events, and $\varepsilon_{s}$ stands for the efficiency to count $\pi^{+}$mesons in cē events. With our se-
lection criteria, $\varepsilon_{\mathrm{h}}$ and $\varepsilon_{\mathrm{cc}}$ present no significant difference: $\varepsilon_{\mathrm{h}} / \varepsilon_{\mathrm{c} \overline{\mathrm{c}}}=1.000 \pm 0.005$ from the Monte Carlo simulation. The efficiency $\varepsilon_{\mathrm{s}}$ can be expressed as

$$
\begin{aligned}
\varepsilon_{\mathrm{S}} & =\mathscr{P}_{1}\left(\mathrm{c} \overline{\mathbf{c}} \rightarrow \mathrm{D}^{* \pm}+\mathrm{X} \text { with } \mathrm{D}^{*+} \rightarrow \mathrm{D}^{0} \pi^{+}\right) \\
& \times \mathscr{P}_{2}\left(\pi^{+} \text {as measured }\right) \times \mathscr{P}_{3}\left(\pi^{+} \text {as fitted }\right),
\end{aligned}
$$

where $\mathscr{P}_{1}$ is the probability to produce $\mathrm{D}^{0} \pi^{+}$from $\mathrm{D}^{*+}$ decays in c $\bar{c}$ events, $\mathscr{P}_{2}$ is the probability to reconstruct and select a $\pi^{+}$meson, and $\mathscr{P}_{3}$ is the probability to count these measured $\pi^{+}$in the fitting procedure.
$\mathscr{P}_{1}$ can be obtained from a measurement by the CLEO Collaboration [6] at $\sqrt{s}=10.55 \mathrm{GeV}$ of the cross section

$$
\sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow \mathrm{D}^{* \pm}+\mathrm{X} \text { with } \mathrm{D}^{*+} \rightarrow \mathrm{D}^{0} \pi^{+}\right)
$$

and averaging over two decay modes of the $\mathrm{D}^{0}$ meson (see table 3): $\mathrm{D}^{0} \rightarrow \mathrm{~K}^{-} \pi^{+}$and $\mathrm{K}^{-} \pi^{+} \pi^{-} \pi^{+}$using the branching fractions of the $\mathrm{D}^{0}$ measured by MARK III [11]. This probability does not depend on a measurement of the branching fraction of the decay $\mathrm{D}^{*+} \rightarrow \mathrm{D}^{0} \pi^{+}$, nor on the ratio of vector to pseudo-scalar charmed meson production. Furthermore the above cross section was measured for the continuum with a kinematic constraint forbidding the detection of charmed mesons in $\mathrm{Y}(4 \mathrm{~S}) \rightarrow \mathrm{B} \overline{\mathrm{B}}$ events. The probability thus obtained is $\mathscr{P}_{1}=0.308 \pm 0.046$ at $\sqrt{s}=$ 10.55 GeV , in agreement with the value $0.315 \pm 0.046$ deduced from the HRS experiment at $\sqrt{s}=29 \mathrm{GeV}$

Table 3
Computation of the probability $\mathscr{P}_{1}\left(\mathrm{c} \bar{c} \rightarrow \mathrm{D}^{* \pm}+\mathrm{X}\right.$ with $\mathrm{D}^{*+} \rightarrow \mathrm{D}^{0} \pi^{+}$) from CLEO results at $\sqrt{s}=10.55 \mathrm{GeV}[6]$.
$\mathscr{P}_{1}=\frac{\sigma_{\mathrm{D}^{*}}^{0}}{\mathrm{R}_{\mathrm{cz}}^{0} \times \sigma_{\mathrm{h}}^{0}}=0.308 \pm 0.046$
where
$\mathbf{R}_{\mathrm{cc}}^{0}=\sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow \mathrm{c} \overline{\mathrm{c}}\right) / \sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow\right.$ hadrons $)=0.37 \pm 0.02[6]$
$\sigma_{\mathrm{h}}^{0}=\sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow\right.$ hadrons $)=3.33 \pm 0.05 \pm 0.21 \mathrm{nb}[6,12]$
$\sigma_{\mathrm{D}^{*}}^{0}=\sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow \mathrm{D}^{*}+\mathrm{X}\right.$ with $\mathrm{D}^{*+} \rightarrow \mathrm{D}^{0} \pi^{+}$, or $\left.\mathrm{D}^{*-} \rightarrow \overline{\mathrm{D}}^{0} \pi^{-}\right)$

$$
=0.379 \pm 0.046 \mathrm{nb}
$$

$\sigma_{\mathrm{D}}^{0}$ is computed from measurements shown below.

| Decay mode of $\mathrm{D}^{0}$ | $B \sigma_{\mathrm{D}^{*}}^{0}(\mathrm{pb})^{\text {a) }}$ | Branching fraction $B^{\mathrm{b})}$ |
| :--- | :--- | :--- |
| $\mathrm{D}^{0} \rightarrow \mathrm{~K}^{-} \pi^{+}$ | $17.0 \pm 1.5 \pm 1.4$ | $0.042 \pm 0.004 \pm 0.004$ |
| $\mathrm{D}^{0} \rightarrow \mathrm{~K}^{-} \pi^{+} \pi^{-} \pi^{+}$ | $33.0 \pm 3.0 \pm 1.8$ | $0.091 \pm 0.008 \pm 0.008$ |

[^2][8] but where the error on the cross section of cc production, including the $b \rightarrow c$ transition, is not quoted. In the following, the value $\mathscr{P}_{1}=0.31 \pm 0.05$ is used, with the assumption that the fragmentation rate of charm into $\mathrm{D}^{*+}$ does not change from 10.55 up to 91 GeV center-of-mass energy.

The probability $\mathscr{P}_{2}$ to reconstruct and select $\pi^{+}$mesons with our criteria described in section 3 , is deduced from the Monte Carlo simulation: $\mathscr{P}_{2}=0.27 \pm$ 0.02 . The main causes of loss are the momentum selection of $\pi^{+}$between 1.5 and $2.5 \mathrm{GeV} / c$ and the requirement that the $\pi^{+}$is inside a jet free from hard gluon radiation. The error takes into account a shift of $\pm 10 \%$ in the momentum of the $\pi^{+}$from the uncertainty in the fragmentation function of the charm quark.

The proportion $\mathscr{P}_{3}$ of these $\pi^{+}$mesons which are finally fitted from the overall $p_{\mathrm{T}}^{2}$ distribution is also taken from the simulation $\mathscr{P}_{3}=0.78 \pm 0.05$, where the error reflects an uncertainty of $5 \%$ on the slope $B$ of the signal shape.

Finally the important assumption is that the only contribution to the observed accumulation of tracks at low $p_{\mathrm{T}}^{2}$ comes from $\mathrm{D}^{*+} \rightarrow \mathrm{D}^{0} \pi^{+}$decays occuring in $c \bar{c}$ events. The background from the other quark flavours, including $\mathrm{b} \overline{\mathrm{b}}$, is evaluated with the Monte Carlo simulation (table 1) and transforms into an $18 \%$ systematic error on the fitted value of $N_{\mathrm{s}}$. The electron background is negligible within the cuts because, according to the simulation, their $p_{T}^{2}$ slope is large and a variation of $\pm 20 \%$ of their amount would change $N_{\mathrm{s}}$ by only $\pm 1 \%$.
The resulting cross section ratio is thus
$R_{\mathrm{c} \overline{\mathrm{c}}}=0.162 \pm 0.030$ (stat.) $\pm 0.050$ (syst.) ,
where the statistical error results from the fitting procedure and where the various contributions to the systematic error are listed in table 4.
The predicted value of the standard model for the ratio of the partial width $\Gamma_{\mathrm{cc}}$ of the $\mathrm{Z}^{0}$ into cec to the total hadronic width $\Gamma_{\mathrm{h}}$ is [13]
$\frac{\Gamma_{\mathrm{cc}}}{\Gamma_{\mathrm{h}}}=0.171$ (S.M.) .

Table 4
Contributions to the systematic error on $\Gamma_{\mathrm{cc}} / \Gamma_{\mathrm{h}}$.

| Contributions | Systematic error |
| :--- | :--- |
| ratio of global efficiencies $\varepsilon_{\mathrm{h}} / \varepsilon_{\mathrm{cc}}$ | $\pm 0.001$ |
| probability $\left(\mathrm{c} \overline{\mathrm{c}} \rightarrow \mathrm{D}^{*+}\right.$ with $\left.\mathrm{D}^{*+} \rightarrow \mathrm{D}^{0} \pi^{+}\right)$ | $\pm 0.026$ |
| reconstruction and selection of $\pi^{+}$mesons | $\pm 0.012$ |
| shape of the signal in fitting procedure | $\pm 0.010$ |
| choice of the background shape | $\pm 0.027$ |
| background from other quark flavours | $\pm 0.029$ |
| electron background | $\pm 0.002$ |
|  | $\pm 0.050$ |

## 6. Conclusion

An inclusive analysis of $Z^{0} \rightarrow c \bar{c}$ events has been performed at LEP using the low momentum and low $p_{\mathrm{T}} \pi^{ \pm}$mesons produced in the decays of charmed mesons $\mathrm{D}^{*+} \rightarrow \mathrm{D}^{0} \pi^{+}$and $\mathrm{D}^{*-} \rightarrow \overline{\mathrm{D}}^{0} \pi^{-}$. Assuming that in $c \tilde{c}$ events the probability of producing such a low momentum $\pi^{ \pm}$from $D^{* \pm}$ decays is $0.31 \pm 0.05$ [6], the partial width ratio is found to be
$\frac{\Gamma_{\mathrm{c} \overline{\mathrm{c}}}}{\Gamma_{\mathrm{h}}}=0.162 \pm 0.030$ (stat.) $\pm 0.050$ (syst.) ,
in agreement with another measurement [14] and with the standard model prediction of 0.171 [13]. From our previous measurement of the total hadronic width [2],
$\Gamma_{\mathrm{h}}=1741 \pm 61 \mathrm{MeV}$,
we deduce the $\mathrm{Z}^{0}$ partial width into charm quark pairs:
$\Gamma_{\mathrm{c} \overline{\mathrm{c}}}=282 \pm 53$ (stat.) $\pm 88$ (syst.) MeV .

## Acknowledgement

We are greatly indebted to our technical staffs and collaborators and funding agencies for their support in building the DELPHI detector and to the members of the LEP Division for the superb performance of the LEP collider.
